7 Abstract

- For the live-bearing and egg-laying class of chondrichthyan fishes a three parameter logistic 'maternity' function with a variable upper asymptote, P_{Max} , can be used to predict the average probability of a female 10 giving birth or laying eggs in a season. Although fundamental to calculating the reproductive capacity of a population, few studies report maternity functions, with maturity functions often used as a proxy. Applying 11 logistic models to simulated and empirical data showed that it was feasible to estimate P_{Max} from maternal 12 data and that accuracy, bias, and confidence interval coverage often improved compared to when a fixed 13 value was used. However, sample sizes of 100 - 200 maternal females were typically required for accurate 14 estimation of P_{Max} . While maturity parameters could be estimated with greater accuracy, substituting them 15 for maternity parameters overestimated lifetime reproductive output. Greater use of maternity functions has 16 the potential to improve calculation of reproductive output in quantitative populations models. In addition 17 18 to improvements in parameter estimation, this method involves fewer assumptions and enables statistical 19 inferences to be made on frequency of reproduction.
- 20 Key words Logistic regression; reproductive biology; maturity ogive; fisheries management

21 1 Introduction

Many ecological and evolutionary applications need quantitative data on the reproductive capacity of a 22 population and in fisheries science this information forms the basis of widely-used management reference 23 24 points such as spawning stock biomass (Hilborn and Walters 1992, Quinn and Deriso 1999). Calculating reproductive capacity requires data on the sexually mature proportion of the population contributing to 25 reproduction at a given size or age. For most populations of teleost fishes a simple two-parameter logistic 26 regression function (2PLF) is sufficient to model this process using dichotomous sexual maturity stage data 27 (immature / mature) from a sample of individuals (Jennings et al. 2001, King 2007). While the mathematical 28 formulae and methods of statistically estimating parameters for a 2PLF vary, the estimated values are similar 29 and can be obtained with the built in generalised linear model (GLM) programs in most modern statistical 30 software. 31 In chondrichthyan fishes (sharks, rays, and chimaeras), the process of maturation can be modelled in a similar 32 manner to teleost fishes with a simple 2PLF; however, for the intents and purposes of calculating reproductive 33 capacity, chondrichthyans differ in several ways to most teleosts. Firstly, in many chondrichthyans the 34 duration of the reproductive cycle is longer than a year, meaning the proportion of mature females that will 35 give birth in the population in a given season is less than one (Frisk et al. 2005, Dulvy et al. 2008, Rigby 36 and Simpfendorfer 2015). Secondly, there may be a lag between when females reach sexual maturity and 37 when they begin reproducing (Harry et al. 2013, Fujinami et al. 2017). This is confounded by the adopted 38 definition of maturity, which can lead to variable estimates of size and age at maturity (Braccini et al. 2006, 39 Walker 2007, Montealegre-Quijano et al. 2014). Finally, because female fecundity is low (usually $\ll 100$ 40 41 embryos), total pup or egg production and recruitment are likely to be closely related to the number of reproductively active females, exhibiting little interannual variability (Taylor et al. 2013). This contrasts the 42 often highly variable relationship between stock size and recruitment in teleost fish, and warrants a precise 43 definition and calculation of reproductive output. For these reasons, unlike in teleosts, a maturity function 44 may not be the most appropriate tool to quantify reproductive capacity. 45

46 1.1 Maternity function

47 Walker (2005) recognised the need for a maternity function, as distinct from a maturity function, to accurately

48 quantify reproductive capacity in chondrichthyans. For this purpose he used a non-linear, three-parameter

49 logistic function (3PLF) of the form:

$$Y_i \sim B(x_i; n_i, P_i)$$

50

$$E[Y_i] = n_i P_i = \frac{\alpha}{1 + e^{-(b_0 + b_1 x_i)}}$$

where the proportion of individuals in a given length or age category, x_i , that are in maternal condition, Y_i , 51 is a binomially distributed random variable, with an expected value equal to the probability of an individual 52 from that category being in maternal condition, P_i , multiplied by the total number of individuals in the 53 category, n_i . If x is a continuous rather than categorical variable (i.e. n = 1), Y_i reduces to a Bernoulli 54 random variable (Zuur et al. 2007). The upper asymptote of the curve, α , controls the maximum value of Y 55 56 as x approaches infinity. The lesser-used 3PLF reduces to the ubiquitous 2PLF when $\alpha = 1$, as is appropriate for most teleost and chondrichthyan populations if modeling maturity (Quinn and Deriso 1999, Roa et al. 57 1999). When $\alpha = 1$, the function also belongs to the class of generalised linear models; logistic transformation 58 of the dependent variable allows Y to be modeled as a linear function of x_i , where b_0 and b_1 are the intercept 59 60 and slope, respectively (Zuur et al. 2007). Alternatively, the model can be expressed in more biologically

$$E[Y_i] = P_{Max} \left(1 + e^{-ln(19) \left(\frac{x_i - x_{50}}{x_{95} - x_{50}} \right)} \right)^{-1}$$

62 where x_{50} and x_{95} are the sizes or ages at which 50% and 95% of the maximum proportion of individuals

63 (P_{Max}) are in maternal condition. Instead of being fit to data on female maturity condition the model is fit

64 to dichotomous data on female maternal condition (non maternal / maternal).

65 Walker (2005) defines individual females as being in maternal condition if they would have given birth or

66 laid eggs by the end of a given year such that they contribute to annual recruitment (age 0+ cohort) at

67 the beginning of the next year. Pregnancy is a necessary, but not sufficient, condition for maternity, and

68 the two conditions are not always synonymous. For example, reproduction in the Australian population of

relevant terms as:

61

69 school shark, Galeorhinus galeus, occurs triennially, such that approximately one third of mature females give birth annually and $P_{Max} \approx 1/3$ (Walker 2005). Gestation lasts 20 months, and includes a protracted 70 71 period of ovulation. Newly pregnant females are not considered to be in maternal condition until the year of pre-recruitment. Walker's (2005) definition is specific to species that reproduce during a single, well-defined 72 73 period of the year, but the concept can be generalised to accommodate asynchronously reproducing species 74 or those that reproduce more than once a year. Numerous authors have adopted Walker's (2005) maternity function, including for species with biennial or 75 longer reproductive cycles (Huveneers et al. 2007, Rochowski et al. 2015, Trinnie et al. 2016) as well as those 76 with annual or shorter reproductive cycles (Trinnie et al. 2009, Mejía-Falla et al. 2012, Harry et al. 2013, 77 Taylor et al. 2016). Techniques have been described for determining maternal output in asynchronously 78 reproducing species (Braccini et al. 2006, Colonello et al. 2016), and maternity functions are also increasingly 79 80 being used directly in shark and ray population assessments (SEDAR 2012, 2017, 2023). 81 Despite an increase in use, only a small fraction of reproductive studies in recent years have reported maternity functions. Classification of maternal condition is more data-intensive than maturity condition, 82 ideally requiring monthly sampling over a year or longer in order to establish the timing and duration of the 83 84 female ovarian and uterine cycles, particularly if there is a resting period between pregnancies. Such data can be difficult and costly to collect for sharks and rays, which are often data-poor and sampled opportunistically. 85 The teleost-oriented foundations of fisheries science have also contributed to the general lack of awareness of 86 maternity functions; Walker (2005) is the sole description on this type of analysis for chondrichthyans and 87 there are no primary literature sources that describe specific methods for chondrichthyan fishes. 88 For practitioners that are aware of maternity functions, lack of information on implementation may also have 90 discouraged use. Walker's (2005) approach to estimating parameters in the maternity function is difficult to reproduce, apparently due to the constraints of the proprietary statistical program first used to implement the analysis. Specifically, the method as described involves adjusting the raw data prior to parameter estimation 92 93 and then weighting it during analysis (Walker 2005). Additionally, the use of a fixed value for P_{Max} , as in the original analysis, has the potential to bias parameter estimates and reduce their standard errors (Motulsky 94

and Christopoulos 2004). Alternative approaches to estimating maternal parameters have also arisen in the literature, indicative of a lack of guidance on implementation. For example, some authors have obtained maternity parameters by fitting a 2PLF to maternity data (Baremore and Hale 2012, Baremore and Passerotti 2013). 98 A consequence of the low uptake in use of maternity functions is that most practitioners undertaking 99 100 population assessments invariably take an ad hoc approach to quantifying maternal reproductive output. 101 This typically involves approximating maternal output using a maturity function. Under such an approach 102 all mature females are tacitly assumed to reproduce in each breeding season (Cortes 1998). Non-annual 103 reproduction is accounted for by weighting fecundity or the maturity function by the assumed (but often unknown) duration of the reproductive cycle (Walker 2005). In some cases, calculations of reproductive 104 105 output may use the age-at-first-reproduction, defined as the mean age at maturity plus the gestation period 106 (Mollet and Cailliet 2002). This accounts for the protracted gestation period of many chondrichthyans, but still assumes that all individuals begin reproducing immediately after maturity. Measures of annual 107

reproductive output that follow this approach are hence built upon a series of assumptions that are rarely

110 1.2 Revisiting the maternity function

111 Wider use of maternity functions in studies of chondrichthyan reproductive biology is needed to improve 112 calculation of reproductive capacity in the quantitative population assessments that are increasingly being 113 used to support fisheries management and prioritize conservation actions (Cortés et al. 2012, Swenson et al. 114 2024). It may also help address the lack of empirical data on the periodicity of chondrichthyan reproductive cycles. Historically, reproductive periodicity has only been determined qualitatively, and has been assumed 115 116 to be fixed (e.g. annual, biennial), despite observations of plasticity in this trait within discrete populations 117 (Higgs et al. 2020, Nosal et al. 2021). Information on reproductive periodicity is contained within maternal data, however the existing approach of fixing P_{Max} in maternity functions prevents statistical inference from 118 being made on these data. Changes to the way in which maternity functions are implemented may also 119 contribute to quantifying uncertainty in reproductive frequency and help understand the temporal stability 120

108

109

tested in practice.

121 of reproductive cycles. To date only a single study on spiny dogfish, Squalus acanthias, has statistically estimated P_{Max} from data (Colonello et al. 2016), and the feasibility of doing so for a wider range of species 122 123 has not been investigated. 124 This study revisits the use of maternity functions with the objectives of providing guidance on implementation and appropriate use. To address this objective a combination of simulated and empirical data were used to 1) 125 evaluate the performance of two alternative methods for estimating maternity parameters, subject to varying 126 127 reproductive frequency, sample size, and gear selectivity, 2) illustrate the effect of not using using maternity functions on calculations of lifetime reproductive output, and 3) outline strategies for making inferences on 128

reproductive frequency from maternity data.

2.1Approach 131

129

134

135

137

138

139

141

132 To assess the feasibility of estimating maternity parameters a simulation study was carried out using the 3PLF 133 to generate data for populations with varying reproductive frequencies (Figure 1). Simulations were conducted for a range of gear selectivities and sample sizes reflective of those typically available in reproductive studies and fishery sampling programs. The performance of three methods in estimating 'true' maternity parameters 136 from simulated data was tested by examining accuracy, bias, and interval coverage. To illustrate the effects of misspecifying maternity parameters, lifetime reproductive output was calculated for each simulated population using parameters derived from each of the methods, and by substituting maturity parameters for maternity parameters. Finally, empirical data from previously published studies were reanalysed to illustrate possible strategies for estimating maternity parameters and making inferences on reproductive frequency. All 140 simulation modelling and data analysis was conducted using the R language [Version 4.2.0] (R Core Team 2022) and the Template Model Builder (TMB) R package [Version 1.9.1] (Kristensen et al. 2016). 142

143 2.2 Simulation

144 2.2.1 Data generation

- Data were generated for the gummy shark, *Mustelus antarcticus*, and school shark, *Galeorhinus galeus*, using parameters from studies conducted on southern Australian populations (Table 1) (Grant et al. 1979, Kirkwood and Walker 1986, Moulton et al. 1992, Walker 1992, Punt and Walker 1998, Walker 2005, 2007).

 Both species are well-studied and were chosen to be representative of fast and slow chondrichthyan life history styles, respectively (Stevens 1999).
- 150 Catch at length data were simulated using a female-only, length- and age-based equilibrium population model 151 (Hesp 2023). The approach involved calculating expected survival and catches per recruit subject to specified 152 life history parameters, gear selectivity, and total mortality. Growth was modelled using a von Bertalanffy 153 growth function with length l, of a fish of age, a, calculated as

$$l(a) = L_{\infty}(1 - e^{-K(a - a_0)})$$

where L_{∞} is asymptotic length, K is the growth coefficient and a_0 is the hypothetical age at zero length. Recruitment into the population was assumed to occur at age 0 with length conforming to a normal distribution. The proportion of fish of length, l, at age, a = 0, was calculated as

$$\Theta_k = \int_{l_k^-}^{l_k^+} f_{a=0}(l) dl$$

where l^- and l^+ are the lower and upper limits of each 1cm length class, k. $f_{a=0}(l)$ is the value of the normal probability density function at age a=0 for a given length, l,

$$f_{a=0}(l) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[\frac{(l-\mu)^2}{2\sigma^2}\right]$$

where mean length, μ , was calculated from the growth curve. The standard deviation, σ was not available for either species so was assumed to be directly proportional to length, with a constant of proportionality of 5%

- 161 i.e. $\sigma = 0.05\mu$ (Table 1).
- 162 Growth in subsequent age classes was modelled using a length transition matrix (Punt et al. 1997, Hall et al.
- 163 2000), $G = g_{j,k}$ that represents the probability that a fish in length class, j, will grow into length class, k,
- 164 over a specified time interval

$$G = \begin{bmatrix} g_{1,1} & 0 & 0 & 0 \\ g_{2,1} & g_{2,2} & 0 & 0 \\ \vdots & \ddots & \ddots & 0 \\ g_{n,1} & g_{n,2} & \cdots & g_{n,n} \end{bmatrix}$$

165 where the elements of the matrix followed the general form of Punt et. al. (1997) and are given by

$$g_{k,j} = \begin{cases} \int_{\infty^{-}}^{l_k^+} f[\phi(l,j)] dl & \text{if } k = 1\\ \int_{l_k^-}^{l_k^+} f[\phi(l,j)] dl & \text{if } k = 1 < k < n\\ \int_{l_k^-}^{\infty^+} f[\phi(l,j)] dl & \text{if } k = n \end{cases}$$

- where l is mean length, f is the specified normal distribution, l_k^- and l_k^+ are the lower and upper limits of
- length class j, and ϕ is a vector of parameters.
- 168 Selectivity in the model was assumed to follow a gamma function based on gillnet selectivity experiments
- 169 (Kirkwood and Walker 1986, Punt and Walker 1998), where the selectivity of an individual in length class, l
- 170 was given by

$$S(l) = \left[\frac{l}{\theta_1 \theta_2}\right]^{\theta_1} exp(\theta_1 - \frac{l}{\theta_2})$$

- 171 where θ_1 and θ_2 are estimated parameters (Kirkwood and Walker 1986). Two selectivity scenarios were
- 172 simulated corresponding to low and high selectivity of the maternal component of the population. For
- 173 consistency between species, gillnet mesh sizes were chosen that would result in peak relative selectivity
- 174 occurring at the lengths equal to 25% and 75% of the population in maternal condition (Table 1).

175 Fishing mortality, F, in length class l, was calculated as

$$F(l) = S(l) \cdot F$$

where F was assumed to be constant and nominally set to 25% of natural mortality, M (i.e. 0.25M). The effects of varying levels of F were not investigated further in this study. Total mortality, Z, in length class, l, was further given by

$$Z(l) = F(l) \cdot M$$

179 The number of fish, N, per recruit in length class, l, that survived to age, a, was calculated as

$$N_{l,a} = \begin{cases} 1 & \text{if } a = 0 \\ N_{l,a-1} \exp(-Z_l) & \text{if } a = 0 < a < A_{Max} \\ N_{l,a-1} \exp(-Z_l)/(1 - \exp(-Z_l)) & \text{if } a = A_{Max} \end{cases}$$

180 where A_{Max} is the maximum age (Table 1). The estimated numbers of fish caught in length class, l, at age, 181 a, was calculated using the Baranov catch equation as

$$C_l = \sum_{a} (F_l/Z_l)(1 - \exp(-Z_l))N_{l,a}$$

To examine the effect of varying sample size, six scenarios were conducted with catch ranging from 50 to 2500 individuals, reflecting a gradient from data poor to rich. Length data were generated by randomly sampling, with replacement, from a vector of length classes, weighted by a vector of probabilities determined from the above catch equation.

Next, dichotomous maturity-at-length data, $\psi(l)$, were randomly generated by simulating from a Bernoulli distribution, $\Psi(l) \sim B(P)$, where P was given by the 2PLF:

$$P = \left(1 + e^{-ln(19)\left(\frac{l - L_{50}}{L_{95} - L_{50}}\right)}\right)^{-1}$$

188 This process was then repeated to generate maternity-at-length data, $\Psi'(l)$, using the 3PLF:

$$\Psi' \sim B(P)$$

189

192

$$P = P_{Max} \left(1 + e^{-ln(19) \left(\frac{l - L'_{50}}{L'_{95} - L'_{50}} \right)} \right)^{-1}$$

Two approaches to estimating maternity parameters were compared: the 3PLF itself (3PLF-estimated) and

190 Finally, 300 iterations were run for each of the 144 unique variables combinations.

191 2.2.2 Estimation approaches

the 3PLF function with a fixed asymptote (3PLF-fixed). Additionally, two approaches using a 2PLF were also 193 194 examined, using maternity-at-length data (2PLF-maternity) and maturity-at-length data (2PLF-maturity). 195 The 3PLF-estimated method was undertaken to validate the utility of this model, which has so far been used 196 in only a single study (Colonello et al. 2016). The 3PLF-fixed is the method described by Walker (2005) 197 and most commonly used in practice. The 2PLF-maternity method was used to examine what effect simply ignoring the upper asmyptote had (i.e. P_{Max} fixed at 1). The 2PLF-maturity method is commonly used to 198 199 approximate a maternity curve, and tacitly assumed to be similar. The resulting maturity curve can then be 200 weighted by the proportion of gravid females to calculate annual reproductive output (although in practice annual fecundity is more often modified, for example halved for a species suspected to reproduce biennially 201 202 (SEDAR 2023)). 203 Only the 3PLF-estimated method involves statistically estimating P_{Max} , which must be subjectively chosen 204 in the case of the 3PLF-fixed and the 2PLF-maturity. P_{Max} is ideally chosen based on detailed study of the ovarian and uterine cycles (Walker 2005), or alternatively based on the proportion of mature females observed 205 to be in maternal condition during sampling (Baremore and Hale 2012, Harry et al. 2013, Trinnie et al. 2016). 206 207 For the purposes of the simulation, the timing and duration of the uterine and ovarian cycles were assumed to be unknown. The following procedure was used to 'guess' the fixed value of P_{Max} in each simulation. P_{Max} 208 was chosen as the proportion of females in maternal condition above the length at which 99% of females 209 were mature, $L > \Psi(L_{99\%})$. In some cases this procedure failed due to there being no maternal females in 210

the simulated data set meeting this criteria. If this occurred, L_{95} was used, followed by L_{50} , and finally the proportion of all mature females in the sample that were in maternal condition. Statistical estimation of all non-fixed parameters in each of the methods was undertaken using maximum likelihood. Nonparametric bootstrapping was used to calculate approximate 50% confidence intervals for the best-fit parameters from 250 resampled data sets.

216 2.2.3 Reproductive output

For each iteration, the per-generation rate of multiplication, R_0 , or lifetime female pup production, was calculated as:

$$R_0 = \int_0^\infty R\beta(a)e^{\int_0^a Mds}da$$

where R and M are the embryonic sex ratio and natural mortality rate (Table 1) and $\beta(a)$ is the age-specific reproductive rate which incorporates $\Psi'(L)$ (Xiao and Walker 2000).

221 2.2.4 Performance

Model performance was evaluated in each iteration where 1) the fitted model successfully converged as indicated 222 by a positive definite Hessian matrix, and 2) the estimated parameters L'_{50} and L'_{95} remained within specified 223 bounds $(0-10^4)$. An iteration was also not attempted if there were no maternal females in the randomly 224 225 generated sample. Model performance was evaluated by quantifying accuracy, bias, and interval coverage for L'_{50} , P_{Max} and R_0 . Bias was quantified using the mean relative error, MRE = mean[$(x_{\text{Estimated}} - x_{\text{True}})/x_{\text{True}}$] 226 and accuracy using the mean absolute relative error, MARE = mean $|[(x_{\text{Estimated}} - x_{\text{True}})/x_{\text{True}}]|$. Interval 227 228 coverage measures the ability of the model to capture uncertainty and was calculated by taking the proportion 229 of the estimated parameters for each simulation that fell within the 50% confidence intervals (Rudd and 230 Thorson 2018). For a well-performing model, approximately 50% of parameters would be expected to fall withing the nominal 50% confidence intervals. 231

232 2.2.5 Empirical case study

An empirical case study was also undertaken to show how maternity functions can be used in practice. 233 Data from two studies of the reproductive biology of the sandbar shark, Carcharhinus plumbeus, in the 234 Gulf of Mexico and western North Atlantic Ocean were combined and reanalysed using both 3PLF methods. 235 The sandbar shark is a relatively long-lived ($A_{Max} = 33 \text{ years}$) and slow growing species ($K = 0.12 \text{ yr}^{-1}$) 236 with a protracted reproductive cycle lasting longer than a year (Springer 1960). The Gulf of Mexico and 237 238 western North Atlantic Ocean population has been considered overfished since the late 1970s (Sminkey and Musick 1995) and during the 2000s detailed studies of sandbar shark reproductive biology and growth were 239 240 undertaken for stock assessment purposes (Baremore and Hale 2012, Piercy et al. 2016). In their study, 241 Baremore and Hale (2012) estimated maternity parameters using the 2PLF-maternity method, weighting 242 the final curve by 0.37 based on the proportion of pregnant females observed, most closely aligning with a triennial reproductive cycle. Piercy et al. (2016) did not estimate maternity parameters but also suggested 243 244 that the average reproductive cycle was likely to be longer than two years based on examination of ovarian follicles. To examine relative support for either a biennial or triennial reproductive cycle, 3PLF-fixed models 245 246 were fit with P_{Max} estimated and fixed at 0.5 and 0.33, respectively.

247 3 Results

248 3.1 Simulation study

Parameter estimation was generally straightforward; with sample sizes > 50 a convergence success rate of $\geq 95\%$ was achieved in all scenarios (Figure S1, Table S1). Overall, convergence and parameter boundary failures were most common with the 2PLF-maternity method which essentially involved fitting data to an under-parameterized model where P_{Max} was always fixed at 1. In addition to convergence failures, 12 simulations also generated zero maternal females, and were discarded.

When using the 3PLF methods model performance typically declined as the periodicity of the reproductive cycle increased. This is seen in the positive correlation between $\widehat{L'_{50}}$ and $\widehat{P_{Max}}$, whereby true underlying P_{Max} affected the magnitude and direction of bias in these parameters (Figure 2). With lower values of P_{Max}

257 it appeared to be more difficult for the model to separate the point of inflection in the logistic model and the 258 upper asymptote. As true underlying P_{Max} decreased there was also a greater potential for positive bias in 259 P_{Max} . Additionally, longer reproductive cycles resulted in fewer females in maternal condition, which was associated with larger bias (Figure 2). 260 261 For the 3PLF methods, parameter estimates tended to be biased high at lower sample sizes (Figure S2, Figure S3). In some scenarios, particularly with sample sizes ≤ 250 , fixing the asymptote was effective at 262 reducing bias, although for larger sample sizes neither method was clearly preferable (Figure S2, Figure S3). 263 The accuracy of parameter estimates varied considerably across different combinations of variables used and 264 among parameters (Figure S4, Figure S5). Again, in some scenarios with smaller sample sizes ≤ 250 , fixing 265 the asymptote improved accuracy with the 3PLF methods, although at larger sample sizes better accuracy 266 was achieved by estimating P_{Max} (Figure 3). Overall, P_{Max} was comparatively more challenging to estimate 267 268 accurately than L'_{50} (Figure S4, Figure S5). 269 While the 3PLF-fixed method was in some cases able to reduce bias at lower sample sizes, a trade off in the use of this method was poorer interval coverage (Figure 4, Figure S6). For most simulations, interval 270 coverage for $\widehat{L'_{50}}$ was well below the expected level of 50%, irrespective of sample size. In contrast, for the 271 3PLF-estimated method interval coverage oscillated around 50% for both $\widehat{L_{50}}$ and $\widehat{P_{Max}}$. 272 273 Differences in life history and gear selectivity played an important role in the ability to obtain accurate and unbiased maternity parameters. Certain combinations of variables in the simulated data resulted in 274 few females in maternal or immature condition, making parameter estimation difficult (Figure S8, Figure 275 S9). This was particularly the case for P_{Max} which required a relatively high maternal sample size to enable 276 277 accurate parameter estimation (Figure 5). These effects were not necessarily consistent between species 278 and seemed to reflect differences in the underlying population length structure. For example, in biennial 279 low selectivity scenarios for gummy sharks ~60% of individuals were immature compared to ~50% in the corresponding scenarios for school sharks (Figure S9). 280

Overall, the 2PLF-maternity method performed the poorest. Ignoring P_{Max} introduced a fixed bias in this

parameter that increased in magnitude as reproductive periodicity increased (Figure S3). This manifested

281

282

283 in an overestimation of L'_{50} that was exacerbated by gear selectivity effects (Figure S2). In contrast, using 284 a maturity function to approximate the maternity function (2PLF-maturity method) resulted in relatively 285 good performance. L_{50} could usually be estimated with a higher accuracy than L'_{50} . For the gummy shark, where L_{50} and L'_{50} were relatively similar, using the 2PLF-maturity method led to a constant underestimate 286 287 of L'_{50} of approximately 2%, exceeding the performance of the 3PLF-methods at most sample sizes. 288 The effect of the different methods in ultimately calculating R_0 varied considerably across the various scenarios. For school sharks, estimating P_{Max} , was the most effective way to minimize bias in most scenarios (Figure 289 S10). Substituting maturity parameters (2PLF-maturity method) led to a median overestimation of R_0 by 290 3.4% across all scenarios, while the 2PLF-maternity method led to a median underestimate of 11.1%. (Figure 291 292 S10). In contrast, for the gummy shark substituting maturity parameters led to a median overestimation of R_0 of just 1% across all scenarios which outperformed the 3PLF methods in many instances (Figure S11). 293 Using the 2PLF method for gummy sharks led to a median overestimate of R_0 of 22% (Figure S10). For both 294 295 species, better accuracy in calculating R_0 was achieved with the 3PLF methods, with the 3PLF-estimated 296 method performing best in most scenarios tested (Figure 6, Figure S12). For gummy sharks the 3PLF-fixed 297 method performed best at lower sample sizes and lower values of P_{Max} .

298 3.2 Empirical case study

Maternal data were re-analysed for 1087 sandbar sharks including 640 mature individuals of which 32% were 299 in maternal condition. Using the 3PLF-estimated method, the maximum likelihood estimate for $\widehat{P_{Max}}$ was 300 301 0.48 (Table 2). Despite having a sample size of > 600 mature females, the proportion of maternal individuals at length was still uncertain and $\widehat{P_{Max}}$ was estimated to lie between 0.39 and 0.60 with 95% confidence (Figure 302 7). For 3PLF-fixed models a value of $P_{Max}=0.5$ was strongly supported ($\Delta_{AIC}=14.15$) over the alternative 303 fixed value of $P_{Max} = 0.33$. The model with $P_{Max} = 0.5$ also outperformed the 3PLF-estimated method 304 $(\Delta_{AIC} = 1.86)$. Given the fixed model had one fewer estimated parameter, both models had essentially the 305 306 same level of support given the data (Burnham and Anderson 2002).

307 4 Discussion

Relatively few reproductive biology studies have used maternity functions to model maternal reproductive output in chondrichthyan fishes. Where they have been employed the approach has typically been to use a three parameter logistic function with a fixed, user-defined value for the upper asymptote, P_{Max} . Here we show that it is feasible to estimate P_{Max} from maternal data, in turn enabling statistical inferences on reproductive periodicity. Applying 3PLF models with estimated and fixed values of P_{Max} to simulated data showed that accuracy, bias, and confidence interval coverage often improved when P_{Max} was estimated. Using a fixed value for P_{Max} in some cases reduced bias. Overall, however, relatively large sample sizes were needed to accurately estimate P_{Max} , particularly with longer reproductive cycles. This study also demonstrated that, in some cases, recruitment was overestimated when maturity data were used to approximate maternal data and inaccurate if P_{Max} was ignored when estimating maternity parameters. Based on these findings we outline considerations for practitioners using these methods and illustrate how they can provide novel insights into reproductive biology. We conclude by discussing the advantages of adopting this approach and future directions.

321 4.1 Implementing maternity functions

Using simulated data to compare the relative performance of the 3PLF-estimated and 3PLF-fixed methods subject to a range of variables showed that it was feasible to estimate P_{Max} , but was difficult to do so accurately. For non-annual reproductive cycles, > 100 school sharks and > 200 gummy sharks in maternal condition were typically needed to estimate P_{Max} with <10% MARE (Figure 5). This indicates that the both sample size requirements and levels of uncertainty are likely to be larger than conventional logistic maturity analysis (Roa et al. 1999). In the case of the gummy shark this inaccuracy led to the 2PLF-maturity method performing comparably or better than the 3PLF methods in minimizing bias in R_0 (Figure S11). Relatively wide confidence intervals were also obtained for P_{Max} in the empirical analysis for sandbar sharks, even with a total sample size of > 1000 females, 206 of which were in maternal condition. A similar sample size was used by Colonello et al. (2016) to estimate plausible values of P_{Max} and maternity parameters for south Atlantic spiny dogfish.

333 The simulation study also also identified some situations where it may be preferable to fix P_{Max} , particularly 334 at lower sample sizes (≤ 100 individuals total). Providing clear guidelines on this is difficult as model 335 performance was species-specific and influenced by life history and gear selectivity. The success of any analysis using a fixed value also ultimately depends on the analyst choosing a suitable value. The potential 336 337 to introduce a greater level of bias through the incorrect selection of P_{Max} should also be considered if using 338 this approach (Natanson et al. 2019). 339 Together, these results suggest that data requirements of the 3PLF analyses may be prohibitively large 340 for many chondrichthyans and therefore best suited to use on commercially captured species where large 341 sample sizes can be obtained (Oddone et al. 2010, Tribuzio and Kruse 2012). For smaller samples sizes, placing a prior or penalty on P_{Max} may also help overcome issues of parameter inaccuracy, enabling existing 342 information about reproductive periodicity to be incorporated from other populations or closely-related 343 344 species (Smart and Grammer 2021). Information on length at maturity, which is likely to be relatively easier to estimate, may also be informative in the development of priors, with L_{50} effectively providing a lower 345 346 bound for L'_{50} . 347 For data-poor chondrichtyan species, or where data on pregnant females are sparse or unattainable, the 348 current practice of using maturity parameters as a proxy for maternity parameters will likely still be the only option. From this perspective, the outperformance of the 3PLF-methods by the 2PLF-methods for the 349 350 gummy shark in several simulations is encouraging. However, the extent to which maturity parameters can 351 provide a good approximation of maternity parameters may be species-specific, depending on how close L_{50} is to L'_{50} . While several studies have shown these parameters to be similar (Walker 2007, Soto-López et al. 352 2018), L'_{50} is more frequently shifted to the right of L_{50} (Braccini et al. 2006, Montealegre-Quijano et al. 353 2014, Colonello et al. 2016, Palacios-Hernández et al. 2020), and this length difference can equate to one or 354 more years. For example, Harry et al. (2013) found both spot-tail shark, C. sorrah, and Australian blacktip 355 356 shark, C. tilstoni, began reproducing the year after reaching sexual maturity. Similarly, Fujinami et al. (2017) 357 found A'_{50} to be 1.4 years older than A_{50} in blue sharks.

More research is needed to understand the relationship between size at maturity and maternity and variability

358

within and among taxa. In general, this study confirms Walker's (2005) assertion that the common practice of weighting the maturity curve by the frequency of parturition overestimates recruitment. This study also confirms that fitting a 2PLF to maternal data when $P_{Max} < 1$ (effectively ignoring P_{Max}) is likely to result in biased parameters and can also overestimate recruitment. While not widely used, this approach has been undertaken in several studies (Baremore and Hale 2012, Mejía-Falla et al. 2012, Baremore and Passerotti 2013, Rambahiniarison et al. 2018).

The empirical analysis carried out using data for the sandbar shark illustrates how novel insights can be

365 4.2 Empirical study

359

360

361

362

363

364

366

367 gained from maternal data by estimating P_{Max} . Detailed reproductive studies of the western North Atlantic population by Baremore and Hale (2012) and Piercy et al. (2016) were ambiguous about the frequency of 368 reproduction. In both studies, the low proportion of pregnant females and bimodality in ovarian follicle size 369 370 led the authors to conclude that the reproductive cycle was most commonly triennial or possibly longer at 371 the population level. Reanalysis of these combined data sets using the 3PLF-estimated method, however, resulted in a maximum likelihood estimate of $\widehat{P_{Max}} = 0.48$, considerably larger than 0.37 - the proportion of 372 373 pregnant mature females observed by Baremore and Hale (2012). Similarly, based on AIC values, a fixed value of $P_{Max} = 0.5$ had a much higher relative plausibility than a value of 0.33 (Table 2). 374 This unexpected result may be related to the gradual attainment of asymptotic maternal status. Maturity 375 in sandbar sharks appears to occur over an extended size range. L_5 and L_{95} are 146cm and 176cm – a 376 377 length interval that corresponds to around seven years given the sandbar shark's slow growth rate (Hale and Baremore 2013). With females maturing over a broad range of sizes and ages, it is possible that smaller females 378 reproduce less frequently, while larger sharks may ultimately be capable of reproducing biennially. Given that 379 few females appear to attain this size (Hale and Baremore 2013), the modal reproductive frequency is still 380 likely at least triennial within the population. Further work would be required to confirm this hypothesis, 381 382 however, such an outcome would have important implications for management; not only are larger females more fecund (Baremore and Hale 2012), they also reproduce more frequently. This implies that size selective 383 fishing or the removal of larger and older female sharks could have a disproportionately greater impact on 384

385

386

4.3 Advantages and future directions

Despite the simplicity of the 3PLF-estimated method, it nonetheless represents a conceptual shift for 387 388 chondrichthyan reproductive and population biology. Until now reproductive periodicity has largely been determined qualitatively from observations of female reproductive biology or inferred based on circumstantial 389 evidence. Using the 3PLF-estimated method to estimate P_{Max} within a maternity function transforms it 390 391 from a nuisance parameter to one of direct inferential interest that can be seen as a valuable output of the modelling process itself. In addition to the potential benefits of using this method to improve estimation of 392 maternal parameters, there are also a range of other advantages that arise from estimating P_{Max} . 393 394 One benefit of this approach is that it reduces the need for subjective modelling assumptions relating to 395 P_{Max} . Such assumptions can have important implications for population modelling. For example, due to 396 uncertainty in temporal and spatial frequency of reproduction in sparsely-spotted stingarees, Urolophus paucimaculatus, Trinnie et al. (2014) estimated maternity parameters for ten plausible scenarios. In stock 397 assessment of western North Atlantic sandbar sharks a breeding frequency of 2.5 years was assumed to 398 399 account for uncertainty in the duration of the reproductive cycle (SEDAR 2017). More commonly, practitioners have chosen fixed values of the form $P_{Max} = 1/n$, where n is the apparent 400 401 duration of the reproductive cycle in years. This process also has the potential to introduce bias if a small proportion of females reproduce more or less frequently than the larger population. Long-term study of 402 403 offspring from genetically profiled lemon sharks, Negaprion brevirostris, confirmed that most individuals reproduced biennially, but also revealed some cases of triennial reproduction (Feldheim et al. 2014). Statistical 404 estimation of P_{Max} from data avoids these decisions and enables uncertainty in this parameter to be included 405 406 in subsequent population models. Estimation of P_{Max} using the 3PLF-estimated method may also be a means to resolving the longstanding 407 408 question of reproductive frequency in some rare and threatened chondrichthyans. White sharks, Carcharodon 409 carcharias, and whale shark, Rhincodon typus, are two examples of intensively studied species where only

410 fragmentary observations of female reproductive biology exist (Joung et al. 1996, Sato et al. 2016). In 411 both species lack of data on reproductive frequency is a major impediment to population modelling and 412 the development of management strategies (Huveneers et al. 2018, Bowlby and Gibson 2020). With many of these populations the focus of ongoing monitoring, non-lethal methods for assessing maternal state may 413 414 eventually provide a way of collecting sufficient data for estimation of P_{Max} (Sulikowski et al. 2016). A logical progression from estimating P_{Max} is the consideration of alternative functional forms for this 415 parameter such as time- or space-varying P_{Max} or more complex length- or age-dependent forms (Winton 416 et al. 2014). Despite the diverse range of reproductive modes found in chondrichthyan fishes, the current, 417 418 limited knowledge of maternal investment has typically investigated variables such as litter size and pup 419 condition (Hussey et al. 2010). Little is known about how reproductive frequency varies as a function of size or age, in response to environmental effects, or at changing population densities. Better understanding of 420 421 these factors has the potential to improve understanding reproductive strategies and is, in many cases, of 422 direct relevance to management.

423 5 Acknowledgements

We thank John Carlson and all NMFS staff who were involved in collecting the sandbar shark reproductive
data used in this study. We also thank Alex Hesp for valuable comments on an early draft of this paper and
generosity in sharing R code. We are grateful to three anonymous reviewers for their detailed and constructive
comments.
